DESCRIPTION

AUTHENTICATION-DATA ISSUING SYSTEM BASED ON UNIQUE TIME,
RECORDING MEDIA FOR STORING AUTHENTICATION DATA
5 ISSUED BY THE AUTHENTICATION-DATA ISSUING SYSTEM AND
AUTHENTICATION DATA VERIFYING SYSTEM

TECHNICAL FIELD

The present invention relates to an authentication
10 data issuing system based on unique time generation, a
recording media for storing authentication data issued by
the authentication-data issuing system and an
authentication data verifying system, which exercise
general control of information issued by particular
15 computers, verify authentication data issued by some of
the computers and thereby effectively avoid damages that
would be caused by any person stealing the authentication
data.

20 BACKGROUND ART

Today, various prepaid cards, each prestoring money
amount information corresponding to a certain amount of
money paid in advance, are being widely used in various
commercial transactions, such as for using railroad
25 facilities and public telephones and playing with
Japanese pinball (hereinafter "pachinko") game machines.
These prepaid cards are inserted into card reader/writers

attached to or contained in various pieces of equipment,
such as automatic ticket checkers, automatic ticket
vending machines, public telephones and game machines,
where each amount due is subtracted from the remaining
5 balance on the card and the prestored money amount
information is rewritten accordingly.

Besides, in various banking agencies and the like,
account transfer services using personal computers and
public telephone lines have come into wide use, and it
10 is expected that every banking and currency settlement
service will be conducted through an electronic currency
system in the near future (as disclosed in, for example,
Japanese Patent Publication No. HEI-7-11723).

Recently, an increasing number of persons have
15 been attempting to tamper or copy the stored data on the
prepaid cards without due authorization, so that prepaid
card issuing companies are exercising, against such
fraudulent attempts, preventive measures that include
encryption and scrambling of the stored data. In the
20 account transfer and various electronic business
transactions, many persons have been attempting to
acquire other person's authentication data in a
fraudulent manner, in order to make unfair benefits by
pretending to be the true prepaid card holder.

25

DISCLOSURE OF THE INVENTION

The present invention has been made in view of

such inconveniences encountered by prior techniques and seeks to provide an improved technique which, using a unique time generating device previously proposed by the applicant of the present application (in PCT/JP/02433),
5 can effectively avoid damages that would be caused by any person stealing authentication data.

In order to accomplish the above-mentioned object, the present invention provides an authentication-data
10 issuing system based on unique time, the authentication-data issuing system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master computer, the master computer comprising: a unique time
15 generating device including time keeping means for sequentially outputting unit time values at predetermined intervals over a preset time-measuring period that begins at a given start point on a selected date and terminates at a given future end point and accumulating means for
20 ~~sequentially accumulating the unit time values output by~~ the time keeping means so as to constantly measure a changing elapsed time within the time-measuring period; transmitter means for, during communication between the master computer and another of the computers subservient
25 to the master computer, transmitting, from the master computer to the subservient computer, authentication data based on an elapsed time measurement, corresponding to a

given time point, indicated by the unique time generating device; and register means for receiving and registering an issuance history of unique authentication data created and issued by the subservient computer imparting

5 additional data, unique to the subservient computer, to the authentication data transmitted by the master computer.

According to another aspect of the present invention, there is provided an authentication-data
10 issuing system based on unique time, the authentication-data issuing system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master computer, the master computer including a unique time
15 generating device including time keeping means for sequentially outputting unit time values at predetermined intervals over a preset time-measuring period that begins at a given start point on a selected date and terminates at a given future end point and accumulating means for

20 ~~sequentially accumulating the unit time values output by~~
the time keeping means so as to constantly measure a changing elapsed time within the time-measuring period. Each of the computers subservient to the master computer comprises: receiver means for, during communication with
25 the master computer, receiving authentication data based on an elapsed time measurement, corresponding to a given time point, indicated by the unique time generating

device of the master computer; issuer means for creating and issuing unique authentication data by imparting additional data, unique to the subservient computer, to the authentication data received via the receiver means
5 from the master computer; and transmitter means for transmitting, to the master computer, an issuance history of the unique authentication data created and issued by the issuer means.

According to still another aspect of the present
10 invention, there is provided an authentication-data issuing system based on unique time, the authentication-data issuing system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master
15 computer, where each of the computers subservient to the master computer comprises: a unique time generating device including time keeping means for sequentially outputting unit time values at predetermined intervals over a preset time-measuring period unique to the
20 ~~computer that begins at a given start point on a~~
selected date and terminates at a given future end point and accumulating means for sequentially accumulating the unit time values output by the time keeping means so as to constantly measure a changing elapsed time within the
25 time-measuring period; issuer means for creating and issuing unique authentication data, peculiar to the subservient computer, on the basis of an elapsed time

SECRET

measurement indicated by the unique time generating device; and transmitter means for transmitting, to the master computer, an issuance history of the unique authentication data created and issued by the issuer means.

According to still another aspect of the present invention, there is provided an authentication-data issuing system based on unique time, the authentication-data issuing system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master computer. Each of the computers subservient to the master computer comprises a unique time generating device including time keeping means for sequentially outputting unit time values at predetermined intervals over a preset time-measuring period unique to the computer that begins at a given start point on a selected date and terminates at a given future end point and accumulating means for sequentially accumulating the unit time values output by the time keeping means so as to constantly measure a changing elapsed time within the time-measuring period. The master computer, exercising general control of the subservient computers, includes register means for receiving and registering an issuance history of data created and issued by each of the subservient computers on the basis of an elapsed time measurement indicated by the unique time generating device of the subservient

computer.

According to still another aspect of the present invention, there is provided a recording media having stored thereon unique authentication data created by any one of the subservient computers, and the recording media is issued by the subservient computer.

According to still another aspect of the present invention, there is provided an authentication-data verifying system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master computer. Each of the computers subservient to the master computer comprises: reading means for reading unique authentication data issued by any one of the subservient computers on the basis of information received from another of the subservient computers, or reading unique authentication data issued by any one of the subservient computers and recorded on a recording media; transmitter means for transmitting the unique authentication data read by the reading means to the master computer for subsequent collation thereby; and receiver means for receiving from the master computer a result of collation between an issuance history of the unique authentication data by each of the subservient computers registered in the master computer and the unique authentication data transmitted by the transmitter means.

According to still another aspect of the present invention, there is provided an authentication-data verifying system including a plurality of computers connected with each other via communication lines with one of the computers set to function as a master computer, where the master computer comprises: receiver means for receiving unique authentication data transmitted by transmitter means of any one of the computers subservient to the master computer, the unique authentication data being issued by the subservient computer and read by reading means of the subservient computer; and collator means for collating between the unique authentication data received by the receiver means and an issuance history of the unique authentication data by each of the subservient computers that is registered in the master computer; and transmitter means for transmitting a result of collation by the collator means to receiver means of the subservient computer.

DESCRIPTION OF THE DRAWINGS

Fig. 1 is a network diagram illustrating an authentication-data issuing system, according to a best mode of carrying out the present invention, for issuing prepaid cards to be used for pachinko game machines;

Fig. 2 is a block diagram illustrating a general setup of a unique time generating device employed in the authentication-data issuing system of Fig. 1;

BEST MODE FOR CARRYING OUT THE INVENTION

In PCT Patent Application No. PCT/JP/02433 filed at an earlier date, the applicant of the present application proposed a unique time generating device and

fully explained the concept of "unique time" generated by the device. Unlike the today's commonly-used time concept based on Greenwich Mean Time, the "unique time" is a time concept to linearly count a preset finite time period from the zeroth toward the last second thereof, i.e., to constantly a measure changing elapsed time toward the last second within the preset time-measuring period.

On the basis of such a unique time concept, the present invention provides for authentication of a given computer on a communication network or authentication of a recording media storing thereon authentication data issued by a given computer on the communication network. First, the present invention will be described hereinbelow in relation to a system for issuing and authenticating prepaid cards for use in Japanese pinball, i.e., "pachinko", game machines equipped with card readers (commonly known as CR-type pachinko game machines).

In Fig. 1, reference numeral 1 represents a highest-level master computer of an original card issuer company that issues prepaid cards (prepaid pachinko cards), to which are connected, via network lines, subservient second-level computers 2A, 2B, 2C, ..., 2n of card distributor companies. Further, to the second-level computers 2A, 2B, 2C, ..., 2n of the card distributor companies are connected host computers (such as those

denoted at 3A, 3B, ..., 3n) of affiliated pachinko houses. In each of the pachinko houses, the host computer (such as 3A) collectively manages or exercising general control of individual pachinko (CR-type) pachinko game machines 4 and prepaid card vending machines 5 located within the house. In addition, in each of the pachinko houses, third-level computers are provided within or connected with the host computer (such as 3A).

The above-mentioned highest-level master computer 1 implements a unique time generating device 6 as shown in Fig. 2 by arranging its CPU 7 to provide a time keeping means 9 and accumulating means 10 and also setting a memory 8 to include a storage means 11 for storing a preset time-measuring period and a renewal means 12 for renewing the time-measuring period. Total time value to be counted over the preset time-measuring period may be optionally set, for example, to correspond to a total value of seconds over a period of ten or 100 years, and every elapsed time within the preset time-measuring period is measured by the time keeping means 9 constantly counting the total time value. For example, the total time values for one, ten and 100 years will be as follows:

Total time value to be counted over a one year period = 31,556,925.9747 seconds (one year = 365.2425 days);

Total time value to be counted over a ten

year period = 315,659,250.9747 seconds; and

Total time value to be counted over a 100
year period = 3,155,692,500.9747 seconds

Here, the "total time value to be counted" is
5 expressed in time units of 1/10,000 second measured by
an atomic clock (cesium clock), and a "unique time" is
given by constantly counting the total time value to
identify a changing elapsed time within the preset time-
measuring period. Elapsed time (unique time measurement)
10 is typically calculated from both an accumulated time and
a subtracted time, as shown in Fig. 3. Specifically,
the accumulated time is a time value measured forward or
incrementally from the zeroth second toward the total
time value to be counted, while the subtracted time is a
15 time value measured rearward or decrementally from the
total time value toward the zeroth second.

Alternatively, a unique time measurement may be
calculated from either the accumulated time or the
subtracted time or by adding some variables to the time
20 value.

The accumulating means 10 sequentially accumulates
successive unit time values measured the time keeping
means 9; that is, the accumulating means 10 calculates
an accumulated time T_n from the zeroth second toward the
25 last second of the total time value T_t to be counted as
well as a subtracted time from the last second toward
the zeroth second ($T_t - T_n$), so as to constantly provide

a changing elapsed time within the preset time-measuring period (see Fig. 3). Once the time value accumulated by the accumulating means 10 has reached the predetermined total time value to be counted T_t (i.e., once the

5 counting of all the seconds in the 100 year period has been completed), the time period renewal means 12 in the memory 8 is activated to renew the time-measuring period for another 100 years and instructs the time keeping means 9 to count the renewed time-measuring period. In
10 this way, the unique time generating device provided in the computer is updated once for every 100 years.

Similar unique time generating device is provided in each of the second-level computers 2A, 2B, ..., 2n of card distributor companies A to n directly connected to
15 or subservient to the highest-level master computer 1, the third-level computers 3A, 3B, ..., 3n of the pachinko houses connected to the second-level computers 2A, 2B, ..., 2n and the fourth-level computers of the individual pachinko game machines 4 and prepaid card

20 vending machines 5 connected to the third-level computers 3A, 3B, ..., 3n. All these unique time generating devices provided in the above-mentioned computers are set to indicate unique elapsed time measurements, different from each other, at every given point. For example, as
25 seen from "product 1" to "product n" in Fig. 4, the unique time generating devices are sequentially produced, at intervals of, for example, one second, and they are

set to start measuring time at different points that depend on the production intervals and thus differ in measured elapsed time from each other by one second; for the same reason, they are set to end measuring time at different points that are displaced from each other by one second due to the differences of their time-measurement start points, although the total time value to be counted T_t , i.e., the length of the time-measuring period (e.g., 3,155,692,500.97 seconds), is the same for all the products, i.e., unique time generating devices. Alternatively, the length of the time-measuring period may be made different among these products or unique time generating devices. As shown in Fig. 5, the unique time generating device 6 provided in the master computer 1 may be set as a master device and the total time values T_t of product 1 to product n sequentially produced or supplied on the basis of unique time generation by the master device may be set to progressively become great relative to that of the master device in such a way that each of the products has a total time value T_t greater by one second than that of the preceding product. It may be assumed that all these unique time generating devices including the master device are caused to start measuring time like a stopwatch. This way, all the unique time generating devices including the master device are allowed to start measuring at a same start point up to their unique total

5

10

15

20

25

transmitter means 13 of the master computer 1 is received by the second-level computer of one of the card distributors requesting the issuance (e.g., card distributor A). As shown in Fig. 8, this second-level computer 2A of card distributor A also includes a CPU 15, a memory 16 having provided therein the unique time generating device 2A6, a receiver means 17 and a transmitter means 18. Each of the original authentication data X1a, X2a and X3a received by the receiver means 17 of the second-level computer is temporarily stored into a register means 19 within the memory 16 and then read out from the register means 19 upon request from the host computer of any one of the pachinko houses. If the receiver means 17 of the second-level computer 2A receives a request for issuance of authentication data for 1,000 1,000-YEN-worth prepaid cards, 100 5,000-YEN-worth prepaid cards and 20 10,000-YEN-worth prepaid cards, then the computer 2A reads out the authentication data X1a, X2a and X3a from the register means 19 and imparts thereto unique additional authentication data A1 - A1000, B1 - B100 and C1 - C20, respectively, that are based on elapsed time measurements sequentially output by the unique time generating device 2A6 of the computer 2A. In this way, unique authentication data corresponding to the respective numbers of the 1,000-YEN, 5,000-YEN and 10,000-YEN prepaid cards are created on the basis of elapsed time

measurements sequentially output by the unique time
generating device 2A6; that is, the authentication data
of the 1,000-YEN prepaid cards will be $X1a+A1$ to
 $X1a+A1000$, the authentication data of the 5,000-YEN
5 prepaid cards will be $X2a+B1$ to $X2a+B100$, and the
authentication data of the 10,000-YEN prepaid cards will
be $X3a+C1$ to $X3a+C20$. The thus-created authentication
data are then transmitted from the transmitter means 18
of the second-level computer 2A to the host computer 3A
10 of the pachinko house A. At the same time, the computer
2A of card distributor A erases the identification,
actually issued to the pachinko house's host computer
(e.g., host computer 3A), from among the issuance-
authorizing identifications corresponding to the
15 authentication data $X1a$, $X2a$ and $X3a$. Once the
identification authorizing issuance of a prepaid card
(issuance-authorizing identification) has run out as a
result of the erasure, new original authentication data
are supplied by the master computer 1.

20 In each of the pachinko houses (the following
description will be made primarily about the pachinko
house A), the receiver means of the host computer 3A
receives the authentication data (e.g., $X1a+A1$, $X2a+B1$
and $X3a+C1$) transmitted by the card distributor A. The
25 host computer of each of the pachinko houses is
constructed in a similar manner to the second-level
computer of Fig. 8 and imparts, to the received

authentication data (e.g., $X1a+A1$, $X2a+B1$ and $X3a+C1$),
identification based on elapsed time measurements
sequentially indicated by the unique time generating
device 3A6 of the host computer. Further, in each of
5 the vending machines 5 capable of dispensing 1,000-YEN,
5,000-YEN and 10,000-YEN prepaid cards to customers, the
unique time generating device (e.g., 5A1-6) provided in
its computer imparts additional identification data based
on elapsed time measurements sequentially indicated
10 thereby. Thus, the vending machine 5 in pachinko house
A can sell, to customers, prepaid magnetic cards 20
which have stored thereon unique authentication data
($X1a+A1+3A*****+5A*****$) as a result of sequential
impartment of various unique data based on the respective
15 elapsed time measurements indicated by the unique time
generating devices at various hierarchical levels, as
shown in Fig. 10.

The ultimate unique authentication data thus
recorded on each of the prepaid cards 20 ($X1a+A1+3A*****+5$
20 $A*****$) is transmitted from the lowest-level computer of
the vending machine 5 to the receiver means of the host
computer 3A of the pachinko house A, which in turn
identifies, from the recorded ultimate unique
authentication data, an up-to-date record or history of
25 prepaid card issuance by the vending machine 5 and
transmits the ultimate unique authentication data to the
receiver means 17 of the second-level computer 2A of

card distributor A shown in Fig. 8. The second-level computer 2A of card distributor A receives, by means of its receiver means 17, the ultimate unique authentication data transmitted from all the associated pachinko houses and stores them into the register means 19 thereof, via which the computer 2A transmits the ultimate authentication data to the receiver means 14 of the highest-level main computer 1. Then, the master computer 1 receives the ultimate unique authentication data transmitted from the computers 2A to 2n of the individual card distributor companies and stores them in the register means 21 within the memory 8.

Note that each of the master computer 1 and subservient computers 2A and 3A of card distributor A and pachinko house stores the received ultimate unique authentication data after collating it with the corresponding authentication data (issuance-authorizing identification) previously sent to the subservient computers. Also, the master computer 1 has prestored therein various attributes of the unique time generating devices provided therein and in all the subservient computers as shown in Fig. 5, so that the master computer 1 rejects the registration, in its register means, of any ultimate unique authentication data containing an attribute that does not agree with the prestored attributes.

In the above-mentioned manner, each of the prepaid

cards 20 sold by vending machine 1 of pachinko house A can be used as a common card universally usable in all the pachinko houses under the control of card distributor company A or of the master computer 1; for example, the
5 issued prepaid card 20 can be used for "pachinko game machine 4" in pachinko house A.

The pachinko game machine of each of pachinko houses A to n ((the following description will be made primarily about pachinko game machine 4) includes a card
10 reader/writer 22 contained in or connected to the lowest-level computer of pachinko game machine 4 as shown in Fig. 11. Reading means 23 of the computer in Fig. 11 reads the ultimate unique authentication data recorded on the prepaid card 22 that is inserted in the card
15 reader/writer 2. The ultimate unique authentication data (X1a+A1+3A****+5A****) read out from the prepaid card 22 by the reading means 23 is transmitted from the transmitter means 24 of the computer to the host computer 3A of pachinko house A. The ultimate unique
20 authentication data received by the receiver means of the host computer 3A is then forwarded, through the receiver means 17 of the computer 2A of card distributor A, to the receiver means 14 of the master computer 1 for necessary collation. The computer 2A of card distributor
25 A or the master computer 1 includes a collator means 26 or 27 as shown in Fig. 6 or 8, which determines whether the ultimate unique authentication data (X1a+A1+3A****+5A*

***) received by the receiver means 14 or 17 has been
duly registered in the up-to-date record or history of
issuance in the register means 19 or 21. When, for
example, the collator means 27 in the computer 2A of
5 card distributor A determines that the unique
authentication data received from the subservient
computer (host computer 3A of pachinko house A) does not
match the data stored in the register means 19, the
unique authentication data is transmitted from the
10 transmitter means 18 of the computer 2A to the receiver
means 14 of the master computer 1, where the data is
collated by the collator means 26. Thus, as long as the
collator means 26 or 27 of the master computer 1 or the
computer 2A of card distributor A determines that the
15 unique authentication data (X1a+A1+3A*****+5A****) received
from the subservient computer (host computer 3A of
pachinko house A) matches the data stored in the
register means 19 or 21, the means 26 or 27 passes the
determination or collation result, through the host
20 computer 3A, to the computer of the pachinko game
machine. Finally, the collation result is received by
the receiver means 25 shown in Fig. 11. The collation
result, of the inserted prepaid card, by the collator
means 26 or 27 thus received by the receiver means 25 is
25 visually shown on a display 28 of pachinko game machine
4 shown in Fig. 11. If, for example, the prepaid card
20 inserted in the card reader/writer 22 is collated

with the registered data and determined, by the collator means 26 or 27 of the higher-level computer, as being a genuine or authentic card rightly issued by any one of the computers under the control of the master computer 1, an authorizing means 29 accepts the prepaid card 20 as authentic and displays various information, such as the type, issue date and remaining units, of the card (see Fig. 11) on the display that is typically in the form of an LCD (Liquid Crystal Display) or CRT (Cathode Ray Tube). If, on the other hand, the prepaid card 20 inserted in the card reader/writer 22 is collated with the registered data, determined, by the collator means 26 or 27 of the higher-level computer, as not matching the data stored in the register means 19 or 21 and such a collation result is received by the receiver means 25, a rejecting means 30 determines the inserted prepaid card 20 as not being an authentic card rightly issued by any one of the computers under the control of the master computer 1 and displays a rejection message "This card is unusable.." on a display 28A in the form of an LCD or CRT; in this case, the rejecting means 30 also instructs the card reader/writer 22 to reject the card as false.

The prepaid card 20 determined as authentic or acceptable by the authorizing means 29 can be used in pachinko game machine 4 by the holder or user of the card. Specifically, if the user, holding a 1,000-YEN prepaid card 20, selectively depresses one of a plurality

of buttons on pachinko game machine 4 to purchase pachinko balls for 500 YEN (50 units) while referring to the information of the card 20 shown on the display 28, the selected purchase information is transmitted from the pachinko game machine's computer, through the host computer 3A of pachinko house A and computer 2A of card distributor A, to the master computer 1 in association with the ultimate unique authentication data stored on the card 20.

10 In the master computer 1 having received the selected purchase information, a renewal means 31 first confirms that the unique authentication data (X1a+A1+3A**
+5A*) received in association with the selected purchase information matches the data previously stored
15 in the register 21 and then creates identification (ID) to authorize the selected purchase. As shown in Fig. 12, the purchase-authorizing ID is created, as authentication-data-updating data Y1a, on the basis of an elapsed time measurement Y1 indicated by the unique time
20 generating device 6 provided in the master computer 1, and the thus-created authentication-data-updating data Y1a is then transmitted from the receiver means 13 to the second-level computer 2A along with the unique authentication data (X1a+A1+3A*****+5A*****).

25 Similarly, in the second-level computer 2A of card distributor A, a renewal means 32 first confirms that the unique authentication data matches the data stored in

00920-15046150

the register 19 and then creates identification data to authorize the selected purchase. As shown in Fig. 12, the purchase-authorizing ID is created, as authentication-data-updating data P1a, on the basis of an elapsed time measurement P1 indicated by the unique time generating device 2A6 provided in the computer 2A, and the thus-created authentication-data-updating data P1a is then transmitted from the receiver means 18 to the host computer 3A subservient to the computer 2A along with the authentication data Y1a created by the master computer 1.

In the host computer 3A as well, further authentication-data-updating data Q1a is created on the basis of a current elapsed time measurement Q indicated by the unique time generating device 3A6 and added to the received data (Y1a+P1), and the added result is transmitted to the pachinko game machine 4. Finally, in the pachinko game machine 4, further authentication-data-updating data R1a is created on the basis of a current elapsed time measurement R1 indicated by the unique time generating device 4A1-6 provided in its computer and added with the data Y1a, P1a and Q1a to provide ultimate authentication-data-updating data (Y1a+P1a+Q1a+R1a), as shown in Fig. 12.

In the computer of the pachinko game machine 4, a renewal means 33 updates the last-stored unique authentication data (X1a+A1+3A*****+5A****) on the prepaid

card 20, on the basis of the updating data
(Y1a+P1a+Q1a+R1a); the updating may be done by erasing
the last unique authentication data or adding thereto the
updating data. What is essential here is that the last-
5 stored unique authentication data should be altered on
the basis of the updating data (Y1a+P1a+Q1a+R1a). The
alteration of the unique authentication data is effected
via the card reader/writer 22, and thus the prepaid card
22 is discharged from the reader/writer 22 with its
10 unique authentication data altered on the basis of the
updating data corresponding to the selected purchase of
pachinko balls for 500 YEN (50 units).

The altered data (updated unique authentication
data) is transmitted to the higher-order computers, one
15 after another, in the hierarchical network structure.
Thus, in the computer 2A of card distributor A, the
renewal means 32 replaces the last unique authentication
data, registered in the register means 19, with the
updated unique authentication data. Then, in the master
20 computer 1 as well, the renewal means 31 replaces the
last unique authentication data, registered in the
register means 21, with the updated unique authentication
data. In this way, the up-to-date record or history of
issuance of the unique authentication data by each of
25 the higher-order computers is updated.

Next time the prepaid card 20 is used at any one
of the pachinko game machines under the control of the

master computer 1, the updated unique authentication data is read out from the card 20 and collated with the data stored in the registers 19 and 20 of the upper-order computers to ascertain its acceptability, in a similar
5 manner to the above-mentioned. At this time, data indicative of the most recent use of the card 20 is displayed on the display 28 of the pachinko game machine 28, as shown in Fig. 13.

As described above, according to the prepaid card
10 issuing and authenticating system, each of the pachinko houses under the control of the master computer 1 imparts, to every inserted prepaid card 20, additional authentication data that is based on respective elapsed time measurements indicated by the individual unique time
15 generating devices, so that various data relating to the issuance and use of the card can be recorded on the card substantially in a time-series fashion. Therefore, every issued prepaid card will have an utterly unique identification and its recorded data will be updated upon
20 insertion into the reader/writer 22. Thus, in a situation where 1,000 or 10,000 false prepaid cards are fabricated which have same data as recorded on a fairly issued authentic card and when someone actually inserts one of the cards into a pachinko game machine, the
25 recorded data on the inserted card is updated in the above-described manner, so that all of the other cards than the initially inserted one will be automatically

rejected as unusable or unacceptable (the original authentic card will also be rendered unusable). With such an arrangement, unfair alteration or tampering or forgery of prepaid cards will end in meaningless effort and thus a thorough self-defense (i.e., safeguard against unfair transfer of the cards to other persons and theft of the cards) is achieved by the present invention.

Whereas the authentication-data-updating data are passed downward to the fourth-level computer in the above-described best mode as shown in Fig. 12, such updating data may be passed from the fourth-level computer upward to the higher-order computers so that same authentication-data-updating data is ultimately shared between the master computer 1 and the fourth-level computer and a prepaid card is issued with the updated unique authentication data. Further, whereas the above-described best mode is arranged such that the data to rewrite data to be recorded on a prepaid card 20 is transmitted to the higher-order computers after the necessary collation is performed on the card 20 inserted in the card reader/writer 22 and then the card 20 is judged to be a fairly issued card, it is preferable that such information exchanges be conducted collectively at one time.

Moreover, whereas in the above-described best mode the unique time generating device is provided in each of the computers of the card distributors, pachinko houses

Namely, in one alternative, the subservient computers

measurement and received from the master computer 1,

combining these unique data is recorded on a prepaid

preferable that the master computer 1 at the highest level in the hierarchical structure should prestore the

authentication data ultimately recorded on the card 20

and registered or updated in the register means 21 (as

that indicate different elapsed time measurements at

every given time point. Each of these unique time

generating devices may be implemented by a software

program installed in the corresponding computer, or may

be provided on an IC chip built in the computer, or may be a discrete driver or generator external to the computer. Further, the unique time generating device may be provided in each of the subservient computers under the control of the master computer 1 with the master computer 1 or owner of the computer 1 operating as an initial or original card supplier (as recited in appended claims 6 and 7). Namely, if the initial card supplier is arranged to prestore contents of data to be generated by the individual unique time generating devices which include their respective elapsed time measurements as well as their respective attributes relative to the master computer 1, it is possible to ascertain via which procedure has been issued the unique authentication data ultimately recorded on the card 20 and registered or updated in the register means 21 (as recited in appended claim 8). In addition, the computer of each of the card distributors may be set to operate as a secondary supplier which supplies the lower-order computers with unique time measurements received from the master computer 1.

In the above-described best mode, each of the vending machines 5 and pachinko game machines 4 has a computer or unique time generating device.

Alternatively, without employing such a system, the host computer of each of the pachinko houses may be set to operate as a lowest-level computer which collectively

controls the individual vending machines 5 and pachinko game machines 4. In this case, the host computer creates and update the unique authentication data and then records the authentication data on a prepaid card
5 that is issued by the vending machine 5 and used in the pachinko game machine 4.

The highest-level computer in the hierarchical structure has been described above as the "master computer" 1 controlling a plurality of other computers.
10 In this sense, any one of the computers of the card distributors and host computers of the pachinko houses may be set to function as the master computer.

Furthermore, the best mode has been described above in relation to prepaid cards for use in pachinko
15 game machines, the present invention may be applied to other prepaid card instruments, such as those for railroads, ships, airplanes, telephones, amusement parks (as recited in appended claim 9). In this case, the system according to the above-described best mode may be
20 provided in the host computers of the card distributors or in the computers of the vending machines or in computers of automatic ticket checkers, telephones or various equipment installed in the amusement parks (as recited in appended claims 38 and 39).

25 As obvious from the foregoing description, the present invention achieves the superior benefit that it can effectively avoid damages which would be caused by

any person stealing or tampering authentication data recorded on recording media.

Examples of Practical Applications:

5 (Example 1)

Now, the present invention will be described in relation to a case where it is used for mutual authentication between computers on a hierarchical communication network. Fig. 14 is a diagram illustrating a hierarchical network of computers installed within a company. In this example, a host or master computer 41 of the company does not itself contain a unique time generating device; instead, such a unique time generating device is provided in each of the lower-level computers subservient to the master computer 41 (as recited in appended claims 4, 5, 6 and 7). Directly connected to the master computer 41 are the computers 42, 43 and 44 of a sales department, accounting department and administration department. Further, the computers 45, 46, 47 and 48 of individual sales sections are connected to the sales department's computer 42, the computers 49 and 50 of individual accounting sections to the accounting department's computer 43, and the computers 51 and 52 of individual administration sections to the administration department's computer 44. The computers subservient to or under the control of the master computer 41 are interconnected via the network for

intercommunication. Each of the computers other than the master computer 41 is provided with a unique time generating device 42A - 52A. As in the above-described best mode, all of these unique time generating devices 5 42A to 52A are set to measure unique or different elapsed times at every given time point. Memory 54 of the master computer 41 includes a data memory 55 in which are prestored various data on the unique time generating devices 42A to 52A provided in the individual 10 lower-level computers under the control of the master computer 41. The master computer 41 also includes a CPU 56, a renewal means 57, a collator means 58, a transmitter means 59 and a receiver means 60. The memory 54 of the master computer 41 further includes a 15 register means 61.

Each of the lower-level or subservient computers 42 to 53 includes a CPU 61, a renewal means 62, a transmitter means 63, a receiver means 64, a reading means 65, an authorizing means 66 and a rejecting means 20 67, as shown in Fig. 16.

For example, when the computer 45 of the first sales section desires to access the computer 50 of the second accounting section to request supply of some accounting-related information, the CPU 61 of the 25 computer 45 creates unique authentication data TKA, peculiar to the computer 45, based on an elapsed time measurement TK indicated by the unique time generating

00520-1504160

device 45A and transmits the thus-created unique authentication data to the higher-level sales department's computer 42 via the transmitter means 63 (see Fig. 16). In turn, the sales department's computer 5 42 forwards the unique authentication data to the receiver means 42 of the master computer 41. Thus, in the master computer 41, the collator means 58 connected to the CPU 56 collates the unique authentication data TKA, received by the master computer 41, with the 10 information on the individual unique time generating devices prestored in the data memory 55, to find which of the subservient computers has created and issued the authentication data TKA. Once the unique authentication data TKA is determined as having been fairly created and 15 issued by any one of the subservient computers as a result of the collation, the master computer 41 registers the authentication data TKA in the register means 61 as part of an up-to-date record or history of unique authentication data issuance by the subservient computer 20 (see Fig. 15). Once the unique authentication data TKA is duly registered in the register means 61, the transmitter means 59 of the master computer 41 transmits information, authorizing the desired access, to the receiver means 64 of the computer 45 of the first sales 25 section by way of the sales department's computer 42.

Thus, in response to the acceptance or authorization of the desired access, the computer 45 of

the first sales section sends, via the transmitter means 63, data to initiate the access to the computer 50 of the second accounting section. At that time, the unique authentication data TKA is sent, as a unique
5 identification of the computer 45, to the receiver means 64 of the computer 50 of the second accounting section along with a request for the accounting-related information.

Then, in the computer 50 of the second accounting
10 section, the reading section 65 reads the unique authentication data TKA from among the received information, and the thus-read authentication data TKA is transmitted from the transmitter means 63, via the accounting department's computer 43, to the receiver
15 means 60 of the master computer 41, where the data TKA is subjected to the collation (see Fig. 16).

In the master computer 41, the collator means 58 collates the received authentication data TKA to determine whether the received data duly matches the data
20 registered in the register means 61. If the authentication data TKA matches the data registered as an up-to-date record or history of issuance of unique authentication data by the subservient computer, the master computer 41 transmits the collated result from its
25 transmitter means 59 to the computer 50 of the second accounting section by way of the accounting department's computer 43.

In this way, the receiver section 64 in the computer 50 of the second accounting section receives the collated unique authentication data TKA. If the collated unique authentication data TKA is judged to be proper data (that has been fairly created and issued by any one of the subservient computers), then the authorizing means 66 in the computer 50 permits further communication with the computer 45 of the first sales section, in response to which the requested accounting-related information is supplied to the computer 45.

If, on the other hand, the collated unique authentication data TKA is judged to be improper data (that has not been fairly created and issued by any one of the subservient computers), then the rejecting means 67 in the computer 50 inhibits further communication with the computer 45 of the first sales section because there is a great likelihood that an unauthorized outsider's computer is pretending to be the computer 45.

With the authentication-data issuing and verifying system in accordance with Example 1 above, each of the computers on the hierarchical network can be authenticated reliably in accordance with data created and issued on the basis of an elapsed time measurement indicated by the unique time generating device provided therein. Thus, it is possible to effectively prevent any third person's computer from unfairly conducting data exchange by pretending to be one of the subservient

computers or intruding into the hierarchical network.

Whereas in Example 1 unique authentication data TKA issued by the computer 45 of the first sales section has been described as being transmitted to the master
5 computer 41 by way of the sales department's computer 42, such data may be transferred directly to the master computer 41. Similarly, data to be collated and resultant collated data may be communicated between the master computer 41 and the computer 50 of the second
10 accounting section directly, rather than by way of the accounting department's computer 43.

Further, when the computer 45 of the first sales section desires further access to the computer 50 of the second accounting section in Example 1, the unique
15 authentication data TKA created and issued earlier may be altered by the renewal section 62 on the basis of an elapsed time measurement indicated by the unique time generating device 45A so that further communication is safely made between the two computers 45 and 50 on the

~~20 basis of the thus-altered unique authentication data in a~~
similar manner to the above-described best mode. In this case, the renewal means 57 in the master computer 41 may update the unique authentication data registered in the register means 61 (as recited in appended claims
25 31 and 32). Also, in such a case, the subservient computers may include a memory means (not shown) for storing the unique authentication data (including the

altered unique authentication data) for use in next
access. Rather than providing such a memory means in
the subservient computers, an alternative arrangement may
be made such that the last-issued unique authentication
5 data TKA is read out from register means 61 in the
master computer 41 as the computer 45 of the first sales
section requests access to the computer 50 of the second
accounting section and additional data based on a new
elapsed time measurement received from the computer 45 is
10 imparted to the authentication data TKA to thereby create
and issue unique authentication data that is updated in
both the master and subservient computers.

Moreover, whereas Example 1 has been described as
carrying out the further access between the subservient
15 computers on the basis of such updated unique
authentication data, unique authentication data may be
created and issued, as a so-called one-time password, for
each access on the basis of an elapsed time measurement
indicated by the unique time generating device provided
20 in the computer requesting the access (as recited in
appended claim 9).

Furthermore, in addition to the arrangement of
Example 1, the accessed subservient computer may also
create and issue unique authentication data via its
25 unique time generating device and transmit the unique
authentication data to the accessing computer by way of
same procedure as taken for the unique authentication

data of the latter computer, so as to permit mutual authentication between the two computers. Moreover, whereas Example 1 has been described in relation to the case where the computers of the individual sections are the lowest-level computers in the company, still-lower-level computers may be connected to the sections' computers for use at various stations or by individual constituent members belonging to the sections and departments (as recited in appended claim 16).

(Example 2)

Next, the authentication-data issuing and verifying system of the present invention will be described in relation to a case where it is applied to mutual authentication among computers of various banking agencies (as recited in appended claims 10 to 15, 20, 22, 38, 39, etc.) This example assumes that account transfers, settlements of account, etc. between the banking agencies are conducted via the respective computers. Further, in each of the banking agencies, various services to individual customers, such as money changing, loaning, payment into accounts and money withdrawal, are recorded in the computer in association with their account numbers and the like. In Example 2, such various operations between the banking agencies and between the banking agencies and their customers are all executed on the basis of unique authentication data.

Fig. 17 is a diagram illustrating a hierarchical

5 computers in the hierarchical network. To the master
computer 70 are connected computers of various lower-
level or subservient banking agencies, such as host

10 computers 74 of credit unions —for simplicity, only one
host computer is shown and will be described for each of
the subservient banking agencies. Further, to the

15 actually performing banking operations, of the associated
banking agencies. Furthermore, to the host computer of
each of the main and local offices and branches are

20 to the on-line terminals, there are provided unique time
generating devices, one for each computer, which count

25 described best mode. Data relating to the individual

unique time generating devices are stored together in a data memory of the host computer 70 of the central bank

5 creates and issues authentication data TL4 on the basis
of an elapsed time measurement indicated by its unique
time generating device and adds the authentication data
TL4 to the authentication data TL3 so as to provide

10 terminal's computer transmits the unique authentication data TL1+TL2+TL3+TL4 to the computer of the local bank's branch as check-settling identification ID along with check settlement information. Prior to the transmission, the issued unique authentication data is sequentially

15 sent to the higher-order computers so that it is
registered in register means (not shown) of the branch's
and local bank's host computers and ultimately in
register means (not shown) of the central bank's host
computer 70. The computer of the local bank's branch,

20 having received the check settlement request, reads the
unique authentication data TL1+TL2+TL3+TL4 from among the
received information and transmits the thus-read data to
the higher-order computers so that the data is

25 70. Specifically, in the central bank's host computer

70, a collator means (not shown) collates the the unique authentication data received from the computer of the

5 received by the branch's computer. If the received data
is authentic data, the branch's computer initiates
procedures necessary for the check settlement on the
basis of permission from the authorizing means;
otherwise, it refuses to execute the check settlement
10 procedures.

15

20_

25

computer creates and issues updated unique authentication data on the basis of the received authentication data, similarly to the unique authentication data creating procedures of Fig. 17. Registration and verification of such updated unique authentication data are performed in a similar manner to the above-described best mode, Example 1 or modifications (as recited in appended claims 27 to 31) and will not be described here to avoid unnecessary duplication.

Although the updated unique authentication data can be generated by updating the last unique authentication data registered in a renewal means (not shown) of the master computer (host computer 70 of the central bank), a similar renewal means may also be provided in each of the lower-order computers to update the content of the unique authentication data stored in the register means of the lower-order computer (as recited in appended claims 32 and 34). In such a case, the renewal means of each of the lower-order computers may retrieve the updated authentication data registered in the highest-level computer of the central bank to thereby update the last unique authentication data stored in the register means of the lower-order computer (as recited in appended claim 33).

Further, in the example of Fig. 17, each of the banking agencies uses unique authentication data not only in transactions with other banking agencies but also in

direct transactions with their customers. Each of the customers normally holds one or more cards 75 (such as a cash card and credit card) associated with his or her account opened at the banking agency, and it is expected

5 that in the near future the customers will also hold electronic money cards (so-called "electronic money")

issued by their banking agencies. Normally, magnetic or

IC cards used as such money-equivalent cards are issued via the terminal computers as shown in Fig. 17, at which

10 time unique authentication data is created, for each of the cards, in accordance with elapsed time measurements

indicated by the individual unique time generating devices on the basis of original authentication data that

is passed from the central bank's computer 70 to the

15 lower-order computers while being imparted additional data in each of the lower-order computers and the thus-

created time unique authentication data is recorded onto the card along with other information such as account

information (including information on the current

20 balance) and credit information (including information on

the maximum limit of loan). Each time the thus-issued

card 75 is used in the terminal computer of a selected banking agency to execute any one of various

transactions, such as payment into account, money

25 changing, money withdrawal from deposits and savings,

deposit of money and inquiry of the current remaining

balance, the unique authentication data is collated and

00000-00000

updated in the master computer 70 (or in any of the lower-order computers). Further, for the electronic money cards which are expected to be widely used in the near future, terminal machines (terminal computers) will be installed in shops, department stores, etc. and connected to the network as shown in Fig. 17, and the unique authentication data on the card 75 will be collated and renewed each time it is put to actual use. As a consequence, the money amount in the account corresponding to the card 75 is updated, i.e., increased or decreased, so that various data are created including the up-to-date record of use of the card 75.

With such an arrangement, theft of the recorded data on the card 75 will end in meaningless effort because the recorded data are automatically altered immediately when the card is put to use.

Further, even in a transaction between the central bank and any one of the subservient banking agencies (such as supply of money, particularly that of electronic money, or inquiry or report between the two), reliable authentication is permitted by creating and issuing unique authentication data to carry out necessary procedures on the thus-issued data. Especially, this arrangement allows the central bank's computer to readily know a total money supply (particularly, that of electronic money), so that the monetary policy of the central bank can be properly managed via its host

computer 70. Other arrangements and operation of the example are similar to those of the above-described best mode, example 1 or modifications and will not be described here to avoid unnecessary duplication.

5 (Example 3)

Fig. 18 is a diagram showing a hierarchical network structure where the authentication-data issuing and verifying system is provided in each of a plurality of computers owned by a railroad company (as recited in
10 appended claims 18, 19, 38, 39, etc.). In the illustrated example, reference numeral 80 represents a host computer of the railroad company, to which are connected subservient computers of individual stations, tourist bureaus and convenience stores --only one
15 station, tourist bureau and convenience store are shown and will be described for simplicity-- that control issuance of railroad tickets. To each of the subservient computers are connected computers contained in or attached to ticket vending machines that issue
20 various tickets with magnetic data recorded thereon, such as ordinary railroad passenger tickets, coupon tickets, commuter passes and platform tickets, as well as prepaid (magnetic) cards for utilizing the railroad facilities. The host computer 80 of the railroad company is also
25 connected with computers of automatic ticket checkers 81 that are placed at the ticket gates of the individual railroad stations to read information recorded on the

prepaid cards and tickets. In this example, a unique time generating device is provided in each of the host computer 80 of the railroad company, computers of the station, tourist bureaus and convenience store and
5 computers of the lowest-level vending machines and ticket checkers 81. Thus, unique authentication data, created and issued by the unique time generating devices on the basis of unique elapsed time measurements in a similar manner to Example 2 above, will be recorded, along with
10 railroad service information indicative of a travel section, type and No. of a reserved seat, term of validity, etc.), onto each of the tickets and prepaid cards sold via the vending machines. To this end, each of the computers of the vending machines and ticket
15 checkers 81 is provided with a reader/writer which reads and write data on the tickets and prepaid cards.

The tickets and prepaid cards issued via the vending machines can be used to pass through the automatic ticket checkers and the prepaid cards can be
20 ~~used to purchase tickets from the vending machines,~~ during which time the unique authentication data recorded on each of these tickets and prepaid cards is read via the reader/writer and then transmitted to the host computer 80 of the railroad company for the subsequent
25 collation. Namely, the host computer 80 collates the received unique authentication data with previously registered data in the register means and then sends the

SECRET

collated result to the ticket checker 81 or vending machine in which the ticket or prepaid card has been inserted. The ticket checker 81 or vending machine, having received the collated result, permits the use of the ticket or prepaid card if the ticket or prepaid card has been determined as authentic, but otherwise it rejects the use of the ticket or prepaid card. Each of the tickets and prepaid cards thus accepted is subjected to necessary rewriting or updating of the recorded railroad service information and the unique authentication data on the basis of authentication data and the like imparted by the higher-order computers in a similar manner to the above-described best mode and examples. The updated data are sent to the host computer 80 of the railroad company to update the previously registered unique authentication data in the register means thereof. For tickets having a specific term of validity, such as commuter passes and platform tickets, the recorded data may be automatically erased via the register means upon expiration of the term.

Such a system for issuing and authenticating tickets and prepaid cards can of course be applied to other transportation companies than railroad companies, such as airline companies, shipping companies and bus companies. In every such application, it is only necessary that information indicative of the shipping, airline or bus services be recorded on the ticket or

prepaid card along with the unique authentication data. Possible examples of the ticket and prepaid card for use with the present inventive system include cards and tickets for amusement parks, lottery tickets and gift certificates issued by department stores, tickets for various recreational facilities, and tickets for automatic vending machines. In every such case, each amount due is subtracted from the money amount (current balance) recorded on the card or ticket and simultaneously the unique authentication data is updated to thereby prevent unfair or unauthorized use of the card or ticket.

(Example 4)

The identification data issuing and verifying system in accordance with the present invention is also applicable to various other types of transaction card, such as cards issued by credit companies, securities companies, insurance companies, loan companies and trust companies. For example, each card issued by a credit company, as shown in Fig. 19, on the basis of information on the customer's credit standing can be used in every member store of the credit company, and the unique authentication data recorded on the card is of course updated each time the card is used. Further, information on every transaction in the member store is sent, along with the unique authentication data, to a host computer 83 of an associated bank as well as a host

computer 82 of the credit company, so that necessary settlement procedures can be performed between the host computers of the bank and credit company on the basis of the unique authentication data.

5 (Example 5)

665220-15040400
10 The authentication-data issuing and verifying system in accordance with the present invention is applicable to computers used by an administrative organ (as recited in appended claim 17) as well as companies and other profit-making and non-profit-making organizations as described earlier in relation to Example 1. Namely, in Example 5, a host computer of the administrative organ is set to function as a master computer, and the other computers used at various
15 stations and by constituent members of the organ are made to function as lower-level computers subservient to the master computer. Access between these computers within the administrative organ is carried out on the basis of unique authentication data similarly to the best
20 mode, examples and modifications as described above.

25 The administrative organ, as shown in Fig. 20, supplies residents with ID cards 85 issued via a card issuing machine 84. At that time, the issuing machine 84 may record unique authentication data created on the basis of respective authentication data transmitted thereto from the host computer 86 and the computer 87 of a main office 86 and added together one after another

(as recited in appended claims 11 and 38). Increased efficiency of the administrative management may be achieved by allowing the residents to get their desired service using the thus-issued ID cards 85 on terminal machines 90 positioned in the main, branch or local office of the administrative organ. In these cases, unfair use of the ID cards by unauthorized persons can be effectively prevented because the unique authentication data recorded on each of the cards is updated immediately every time the card is used on the terminal machine 90.

Whereas the best mode, examples and modifications have been described above mainly in relation to magnetic-type prepaid cards and cash cards, ID cards, etc., the principle of the present invention may also be applied to various other storage media, such as floppy disk and writable CD-ROM. Where the present invention is applied to an IC card, it is possible to incorporate in the IC card a unique time generating device operating on the basis of data received from a higher-level computer, because the IC card can itself contain an electric cell. Further, by attaching the IC card to a handy-type personal computer for connection to communication lines, the computer can work as a lowest-level computer in the hierarchical network structure.

Moreover, whereas the best mode and examples have been described above as communicating the level-specific

authentication data and the ultimate unique authentication data with no particular modification made thereto, it is preferable to encrypt these data via an encoder device. Particularly, it is desirable that these data be appropriately protected from being significantly influenced in a direct manner by a lower-level computer and that the unique time generating devices and their behavior remain invisible.

INDUSTRIAL APPLICABILITY

With the present invention having been described so far, authentication of any one of a plurality of computers interconnected via communication lines or mutual authentication between the computers can be performed with greatly increased accuracy. It is also possible to more accurately authenticate a recording media storing thereon authentication data issued from any of the computers. Further, because the unique authentication data is created and issued or updated or altered every time the recording media having the data stored thereon is put to actual use, the present invention can always grantee a secure transaction even when the unique authentication data is leaked to any third person. Thus, the present invention will find a variety of applications, such as authentication of various money-equivalent transaction instruments such as prepaid cards and cash cards, authentication of tickets,

coupon tickets and electronic money, authentication of personalized ID cards, and computer-based authentication between companies, between banking agencies and between administrative organs.

SECRET F5076760
